## SUMMARY

We describe movement patterns of hatchery-raised, juvenile, spring chinook salmon, Oncorhynchus tshawytscha, using a two-state Markov chain model. The existence of two states, moving and holding, is suggested by anecdotal information from a large radio-tagging study; yet, data describing such observations of small-scale fish behavior are not adequate to estimate transition probabilities directly. Instead, we estimate the transition probability matrix from travel times within each of 11 river segments using a method of moments approach. Bootstrapped confidence intervals are presented. The precision of parameter estimates is improved by incorporating information on river velocity at each observation station. Results suggest differences in fish behavior between river segments.

## 1. Introduction

### 1.1 Background

Recent evidence indicates that substantial mortality of chinook salmon, Oncorhynchus tshawytscha, from the Snake River system, located in Washington, Oregon, and Idaho, occurs in the free-flowing segments of the river above Lower Granite Dam (LGR); yet, there is little information about fish behavior in this area. Previous research has focused on the managed sections of the river below LGR because, historically, poor survival has been attributed to difficulties in passage through hydroelectric facilities (Raymond 1979; Raymond 1988). The current estimates for survival of hatchery-produced, yearling, chinook salmon to LGR, the first dam encountered during seaward migration, have been as low as 15-35\% (Lower Granite Migration Study Steering Committee 1993). The data suggest that improved understanding of behavior during this migration period might enable improved management strategies. Our aim is to develop a stochastic model which provides insights into small-scale fish behavior within the constraints of well-described, larger-scale models of migration processes.

We are interested in developing a simple methodology that can account for the relationship between individual fish behavior and environmental conditions so that the technique might be applied by statisticians and non-statisticians alike. Fisheries radiotagging technology is advancing rapidly as tags get smaller and biologists become more adept at the required surgical and electronic skills. With these advances, there has been a proliferation of radio-tag data; however, methods for analyzing such information are not readily available in the fisheries literature.

The current data set provides some of the first detailed information on fish behavior and in-stream conditions in the free-flowing segments of the river above LGR reservoir. Research on environmental controls of migratory behavior in other species or in other regions provides evidence that factors such as water velocity, water temperature and available light may regulate fish movements (Jonsson 1991; Berggren and Filardo 1993; Independent Scientific Group 1996). The eventual goal of this research is to develop a model which can be used to test for the importance of environmental covariates in regulating behavior. In this paper, we develop a basic model to describe observed patterns of fish movement. We then incorporate mean river velocity into the model to approximate actual river conditions and we examine it's effect on the precision of parameter estimates.

### 1.2 Data

The fisheries data for this analysis are from a large radio-tagging study carried out by the National Marine Fisheries Service. Combination radio transmitter/passive integrated transponder (PIT) tags were surgically implanted into 129 yearling chinook salmon at Lookingglass Hatchery in March 1997. The fish were allowed to recover in the hatchery for approximately two weeks after which time they were released into Lookingglass Creek (LGC). Sample size was reduced by mortality both at the hatchery and during migration. During their migration from LGC to the LGR Reservoir, the fish swam past 12 fixed-site receiving stations. Due to signal strength, antenna orientation, tag failures, and other difficulties with the electronic equipment, each fish was detected at only some
of the stations. Results of this analysis should not be extrapolated to all hatchery fish because comparisons between fish with combination radio transmitter / PIT tags and fish with only PIT tags suggest that the radio-tag may affect migration behavior. For further details on the radio-tagging experiments, see Hockersmith et al. (1998).

In this paper, we describe a technique to model travel time between stations. Travel time was calculated between each pair of contiguous stations (not including the initial release point) for each fish observed at both endpoints. There are between 7 and 31 observations for each of the 11 segments.

River velocity data was collected at 8 of the 12 observation stations during the period of out-migration. Velocity ( $\mathrm{m} / \mathrm{sec}$ ) is defined by the maximum observable surface velocity, which was estimated from the travel time of floating objects over a fixed distance and, where possible, from a boat using a Global Positioning System (GPS). Velocity generally increases as ones moves downstream; however, the final sites on the Snake River are just upstream of LGR Reservoir and velocity decreases significantly in this area.

## 2. Markov Chain Model

### 2.1 Model Summary

To model travel times between stations, a two-state Markov chain model (Guttorp 1995) was selected to meet two criteria. First, the selected model should converge to the inverse Gaussian distribution in the limit. Previous research on migrations of large cohorts of
fish between dams has shown that the distribution of arrival times at dams follows the inverse Gaussian distribution extremely well (Zabel et al. 1998). Second, the model should describe migration patterns observed in the field. During the study, mobile tracking was used to pinpoint fish locations between the fixed-site monitoring stations. Contrary to expectations, fish were often observed to stay in the same location for several days at a time before re-initiating downstream movement. A two-state Markov process is a simple model that meets these two criteria.

We use the two-state Markov model to describe fish behavior between observation opportunities. Our model assumes that fish make movement "decisions" 10 times every hour with the probability of movement dependent on the action taken during the previous time interval. For the basic model, a movement action is defined as a downstream travel distance of 1 km . Velocity is incorporated into the model by allowing fish to move a distance that is dependent on the relative mean velocity in each river segment. We observe a fish at a particular monitoring station after it has moved $L$ kilometers downstream with $L$ defined by the length of the river segment. By defining the model in this way, we can use arrival distributions to estimate biologically meaningful parameters within the transition matrix.

### 2.2 Notation

The following notation will be necessary for the calculations in the next section. Let
$\mathrm{p}_{\mathrm{i}, \mathrm{j}}=$ probability of movement decision $i$ during the current time interval given movement decision $j$ at the previous time interval,
w = wait time to move one unit of distance,
$\mathrm{t}_{\mathrm{k}}=$ travel time through river segment $k$,
$\mathrm{v}_{\mathrm{k}}=$ mean velocity in river segment $k$,
$\mathrm{L}_{\mathrm{k}}=$ length (km) of river segment $k$,
$\mathrm{n}_{\mathrm{k}}=$ number of observations in segment $k$,
$\mathrm{i}, \mathrm{j}=0,1(0=$ stay, $1=$ move $)$, and
$\mathrm{k}=1,2,3, \ldots, 11$.

### 2.3 Estimation of the Transition Matrix Using Method of Moments

The first step in applying the method of moments is to calculate the expected value and the variance of $t_{k}$ using the Markov model. First, we calculate the expectation and variance of $w$. We assume that each fish is initially in the move state, a reasonable assumption given that the fish must be moving to enter each study segment.

$$
\begin{aligned}
\mathrm{E}(\mathrm{w}) & =\sum_{\mathrm{w}=0}^{\infty} w p(w) \\
& =1 \mathrm{p}_{11}+2\left(1-\mathrm{p}_{11}\right)\left(1-\mathrm{p}_{00}\right)+3\left(1-\mathrm{p}_{11}\right)\left(1-\mathrm{p}_{00}\right) \mathrm{p}_{00}+4\left(1-\mathrm{p}_{11}\right)\left(1-\mathrm{p}_{00}\right) \mathrm{p}_{00}^{2} \ldots \\
& =\mathrm{p}_{11}+\left(1-\mathrm{p}_{11}\right)\left(1-\mathrm{p}_{00}\right) \sum_{\mathrm{x}=0}^{\infty}(2+\mathrm{x}) \mathrm{p}_{00}^{x} \\
& =\mathrm{p}_{11}+\left(1-\mathrm{p}_{11}\right)\left(2+\frac{\mathrm{p}_{00}}{1-\mathrm{p}_{00}}\right)
\end{aligned}
$$

And,

$$
\operatorname{Var}(\mathrm{w})=\sum_{w=0}^{\infty} \mathrm{w}^{2} p(w)-E(w)^{2} .
$$

$$
\begin{aligned}
\sum_{\mathrm{w}=0}^{\infty} \mathrm{w}^{2} \mathrm{p}(\mathrm{w}) & =1^{2} \mathrm{p}_{11}+2^{2}\left(1-\mathrm{p}_{11}\right)\left(1-\mathrm{p}_{00}\right)+3^{2}\left(1-\mathrm{p}_{11}\right)\left(1-\mathrm{p}_{00}\right) \mathrm{p}_{00}+4^{2}\left(1-\mathrm{p}_{11}\right)\left(1-\mathrm{p}_{00}\right) \mathrm{p}_{00}^{2} \cdots \\
& =\mathrm{p}_{11}+\left(1-\mathrm{p}_{11}\right)\left(1-\mathrm{p}_{00}\right) \sum_{\mathrm{x}=2}^{\infty} \mathrm{x}^{2} \mathrm{p}_{00}{ }^{\mathrm{x}-2} \\
& =\mathrm{p}_{11}+\left(1-\mathrm{p}_{11}\right)\left(1-\mathrm{p}_{00}\right)\left[\frac{2}{\left(1-\mathrm{p}_{00}\right)^{3}}+\frac{1}{\mathrm{p}_{00}}+\frac{1}{\mathrm{p}_{00}\left(1-\mathrm{p}_{00}\right)^{2}}\right]
\end{aligned}
$$

Therefore,

$$
\begin{aligned}
\operatorname{Var}(\mathrm{w}) & =\mathrm{p}_{11}+\left(1-\mathrm{p}_{11}\right)\left(1-\mathrm{p}_{00}\right)\left[\frac{2}{\left(1-\mathrm{p}_{00}\right)^{3}}+\frac{1}{\mathrm{p}_{00}}+\frac{1}{\mathrm{p}_{00}\left(1-\mathrm{p}_{00}\right)^{2}}\right] \\
& -\left[\mathrm{p}_{11}+\left(1-\mathrm{p}_{11}\right)\left(2+\frac{\mathrm{p}_{00}}{1-\mathrm{p}_{00}}\right)\right]^{2} .
\end{aligned}
$$

We are interested in the moments of $t_{k}$, the total travel time through segment $k$. Total travel time can be calculated as the sum of the individual wait times, $w$. These $w$ are independent given that the initial state for each interval must be 1 . Therefore, $\mathrm{E}\left(\mathrm{t}_{\mathrm{k}}\right)=\mathrm{L}_{\mathrm{k}}\left(\frac{v_{k}}{\bar{v}}\right) \mathrm{E}(\mathrm{w})$ and $\operatorname{Var}\left(\mathrm{t}_{\mathrm{k}}\right)=\mathrm{L}_{k}\left(\frac{v_{k}}{\bar{v}}\right) \operatorname{Var}(\mathrm{w})$, where $\mathrm{L}_{\mathrm{k}}\left(\frac{v_{k}}{\bar{v}}\right)$ represents the number of required movements in segment $k$ at relative velocity $\frac{v_{k}}{\bar{v}}$. The parameter $v_{k}$ is equal to one for all $k$ river segments in the basic model.

The mean and variance of the inverse Gaussian distribution can be calculated from the data as $\bar{t}_{k}$ and $\frac{\left(\bar{t}_{k}\right)^{3}}{\sum_{n_{k}}\left(\frac{1}{t_{k}}-\frac{1}{\bar{t}_{k}}\right)}$ respectively (Folks and Chhikara 1978). The method of moments estimator of the transition probability matrix is calculated by setting the expected value and variance equal to their observed values and solving for $\hat{p}_{00}$ and $\hat{p}_{11}$. The estimates $\hat{p}_{01}$ and $\hat{p}_{10}$ can be calculated simply as $1-\hat{p}_{00}$ and $1-\hat{p}_{11}$. Although these estimators are not necessarily efficient or unbiased, they are reasonable and can be obtained with a minimum of mathematical difficulty (Larsen and Marx 1986).

## 3. Results

### 3.1 Estimated Transition Matrices by River Segment

Tables 1 and 2 display the estimates and bootstrapped 95\% confidence intervals (1000 iterations) for both $\mathrm{p}_{00}$ and $\mathrm{p}_{11}$ by river segment for the basic model (Table 1 ) and for the model incorporating relative velocity (Table 2 ). Confidence intervals were constrained to $(0,1)$. A lack of significant digits in the estimate identifies occasions where the simulated estimates were outside this range. Table 1 also includes the number of observations in each segment and the length of that segment (km).

Velocity is incorporated into the model by multiplying the reach length, $\mathrm{L}_{\mathrm{k}}$, by the relative mean velocity, $\frac{v_{k}}{\bar{v}}$. The effect of incorporating velocity in the model is to reduce or
increase the number of movements required to complete a given river segment. We assume that, where the river is faster, a moving fish travels further with each "decision" to move and vice versa. Table 2 includes the relative velocity in each segment. It contains only nine of the original segments because velocity data was not available for two of the segments.

Table 1 - Estimates and Confidence Intervals for $\mathrm{p}_{00}$ and $\mathrm{p}_{11}$ from the basic model. Number of observations and segment length are included. GRR = Grande Ronde River, SR = Snake River.

Estimates of both $\mathrm{p}_{00}$ and $\mathrm{p}_{11}$ are above 0.80 for all segments in both models although the 95\% confidence interval is often large. In the basic model, it is difficult to distinguish any pattern by comparing the estimates of $\mathrm{p}_{00}$ or $\mathrm{p}_{11}$ between segments of the river or between the two rivers and the confluence.

Patterns are somewhat more apparent in the velocity model. For both $\mathrm{p}_{00}$ and $\mathrm{p}_{11}$, there is a difference between the estimates for the Snake River (discounting the estimate for segment 11 which is only 1 km long) and for the confluence (segment 8 ). Estimates for $\mathrm{p}_{00}$ are all larger in the Snake River than in the Grande Ronde River although this difference does not appear to be significant.

### 3.2 Comparing Precision Between the Two Models

The effect of velocity on the width of the $95 \%$ confidence intervals around $p_{00}$ and $p_{11}$ is described in Figure 1.

Figure 1: Width of $95 \%$ confidence intervals for $\mathrm{p}_{00}$ and $\mathrm{p}_{11}$ for the basic model ( 0 ) and for the model incorporating velocity (V).

In all cases, the width of the confidence interval around $p_{00}$ was reduced or unchanged when velocity was incorporated into the model. The confidence intervals around $\mathrm{p}_{11}$ for segments $2,9,10$, and 11 increased with the addition of relative velocity. These four segments have a relative velocity $<1$. The only other segment with a relative velocity $<1$ is segment 8 , the confluence. The precision of the estimate of $p_{11}$ for segment 8 was unchanged with the addition of velocity.

## 4. Discussion

The two-state Markov model is a simple model to describe the process of migration in juvenile salmonids. Parameters within the transition probability matrix yield information about behavior that would be difficult to observe directly. Using the method of moments
approach described here, estimates of the transition probability matrix can be calculated from arrival time distributions, frequently observed in both radio-tagging studies and in the large PIT tag studies carried out by the National Marine Fisheries Service.

These results suggest that both $\mathrm{p}_{00}$, the probability of a fish staying at one movement opportunity given that it stayed at the previous movement opportunity, and $\mathrm{p}_{11}$, the probability of a fish moving given that it moved at the previous movement opportunity, are fairly large. As a result, we would expect the actual behavior to include fairly long runs of moving and staying. Further, there are rarely large differences between $\hat{p}_{00}$ and $\hat{p}_{11}$ indicating that, on average, time is divided fairly evenly between staying and moving.

In effect, the basic model describes observed patterns (fish behavior plus river movement) while the velocity model describes fish behavior. Table 2 suggests that fish behavior might be different in different segments of the river. The larger values of $\hat{p}_{00}$ in the Snake River indicate that there may be longer runs of staying in these segments, even after adjusting for mean velocity. Mobile-tracking of radio-tagged fish during the study period also identified parts of the Snake River as areas of delay (Hockersmith et al. 1998). Further, this analysis indicates that fish behavior in the region of the confluence may be different than behavior further downstream, perhaps having shorter runs of staying and holding.

The use of mean velocity to adjust the distance traveled in a given movement increased the precision of most estimates of $\hat{p}_{00}$ and $\hat{p}_{11}$. However, further refinements of this
approach might better accommodate changes in river condition by using velocity during the exact time interval in which a fish passes through a particular river segment rather than mean velocity. This approach will also be a useful framework for incorporating other environmental information, such as temperature and available light, into a model that describes small-scale fish movement patterns during migration.

## ACKNOWLEDGEMENTS

We would like to thank Eric Hockersmith and Dr. John Williams at the National Marine Fisheries Service for providing the fish migration data and for supporting the collection of the environmental data. David Caccia and Drs. Jim Anderson, Rich Zabel, Hong Qian, and Dean Billheimer provided critical assistance with the development of this project. This research was supported by the Bonneville Power Administration through Columbia Basin Research and by the National Research Center for Statistics and the Environment, University of Washington, Seattle.
