## ABSTRACT

#### Abstract

A variable span scatterplot smoother based on local linear fits is described. Lonal cross-validation is used to estimate the optimal span as a function $o f$ abscissa value. A rejection rule is suggested to make the smoother resistant against outliers. Computationally efficient algorithms making us of updating formulas and corresponding FORTRAN subroutines are presented.

*Work supported by the 'Department of Energy under coniracts DE-ACO3-76SF00515 and DE-ATO3-81-ER10843, by the Oifice of Naval Research under contract ONR NJ0014-81-K-0340, and by the U.S. Army Ressarch office under contract DAAC29-82-K-0056.

## -2-

## 1. Introduction

A smoother is a procedure that operates on bivariate data $\left(x_{1}, y_{1}\right) \ldots\left(x_{n}, y_{n}\right)$ and produces a decomposition

$$
\begin{equation*}
y_{i}=s\left(x_{i}\right)+r_{i}, \quad i=1 \ldots n . \tag{1}
\end{equation*}
$$

Here $s$ is a smooth function, often simply called tre sonoth, and the $r_{i}$ are residuals. It is possible to formally define at at constitutes a smooth function, and to define measures of smoot ess, but for our purposes an intuitive notion will be sufficient. soothers are used to summarize the association between the preiizt, variabie $X$ and the response $Y$. It was pointed out by cleveland (":; and is a commonly held belief, that when looking at a scatterplot the eye is distracted by the extreme points in the point cloud, i.e., ta fuzzy background, and tends to miss structure in the bulk of the da،a. Augmentation of the plot by smooth is a possible remedy. More formally, smoothers can be regarded as curve estimators; one assumes that the response was generated by adding random noise to a smooth function:

$$
\begin{equation*}
y_{i}=f\left(x_{i}\right)+\epsilon_{i} \tag{2}
\end{equation*}
$$

and considers the smooth $s$ as an estimate for $f$.

Recently scatterplot smoothers have found new use in multipie nonparametric regression (friedman and Stuetzle, 1981). Let $\left(x_{1}, y_{1}\right) \ldots\left(x_{n}, y_{n}\right)$ denote the observations; $x_{i}$ here is a vector in $R P$, not just a single number. Assume as above that $y_{i}=f\left(x_{i}\right)+\epsilon_{i}, 1=1 \ldots n$. Projection pursuit regression constructs an estimate $m$ for $f$ of the form

$$
m(x)=\sum_{i=1}^{M} s_{i}\left(a_{1}, x\right)
$$

where the $\alpha_{i}$ arid suitably chosen unit vectors in RP. For given $\alpha_{i}, s_{i}$ (essentially) is found by smoothing the scatterplet of the residuals $r_{j}^{i-1}=y_{j}-\sum_{k=1}^{i-1} s_{k}\left(\alpha_{k} \cdot x_{j}\right)$ versus $\alpha_{1}, x_{j}$. The smoother described in this report is, up to minor modifications, the ore used in the current projection pursuit regression procedure.

## 2. Basic Concepts

According to the definition above, any procedure that passes a smooth curve thr sugh a scatterplot, for example a procedure that fits a least squares straigh! line, would be called a sinoother. This is not quite what we have in mind. Assume the data are generated according to (2). We are interested in procedures that can approximate $f$ arbitrarily closely, given a dense enough samole, without any conditions on $f$ apart from f being smooth. Such procedures can be based on local everaging. Take s(xi) to be the average of the responses for those observations with predictor values in a neighborhend $N$ of $X_{i}$ :

$$
\begin{equation*}
\left.s\left(x_{i}\right)=\operatorname{ave}: y_{j} \mid x_{j} \in 1\right) . \tag{3}
\end{equation*}
$$

Here "ave" can stand for the arithnetic mear, the median, or mire complicated ways of averaging to be discussed below. A critical parameter to be chosen is the SPAN, the size of the neighborhood over which averaging takes place. It controls the smoothness of s: The bigger the span, the smotter swill be. ro obtain consistency, i.e., to make sure that $s$ gets arbitrarily close to $f$ as the sampling rate increaser. one must shrink the diameter of the neighbo.hood in such a way that the number of sbservations in the neightarhood still grows to
infinity. Shrinking the neighborhood makes the systematic or bias component in the estimation error diminish, while increasing the neighborhood sample size guarantees that the variance component of the error goes to zero as well.

An alternative metrod for nonparametric curve estimation is based on series expansions: make an ansatz for s of the form

$$
s\left(x_{k}\right)=\sum_{i=1}^{M} a_{i} g_{i}\left(x_{k}\right)
$$

where the $g_{i}(x)$ can, for example, be polynomials or trigonometric functions. The constants $a_{i}$ are then determined by fitting the series to the data, most commonly by least squares. The role of the span is played here by $M$, the number of terms included in the model: Trigonometric funcrions have been used with success in cases where the signal is naturally periodic. li the abscissas $x_{i}$ are equi-spaced, the fit is particularly inexpensive to compute using the Fast fourier Transform. Both conditions are usually not fulfilled in the case of scatterplot smoothing, making the method less attractive. The use of polynomials has the drawback that they are not well suited to represent a wide variety of commoniy encourtered functions, for example, functions with asymptotes.

There are, of course, connections between smoothing by series exparision and smoothing by lacal averaging. If the series is fitted by least squarss, the fitted values $s\left(x_{i}\right)$ are weighted averages of the responses $y_{i}$. Depending on the abscissas and the functions $g_{i}(x)$, the weights determining $s\left(x_{1}\right)$ might or might not be concentrated on responses with corresponding predictor values close to $x_{1}$. If they are, the series
expansion method behaves like a local averaging method. An example of this is least squares fit of cubic splines which will be further discussed in Section 9.

## 3. A Simple Nonresistent Smoother

The simplest example for a local averaging type smoother is the moving average, where "ave" in equation (3) denctes the arithmetic mean. The size of the neighborhood 15 usually specified by the sparn, the number $k$ of observations to be included in the averaging. We will assume $k$ to be odd and the abscissas $x_{i}$ to be in increasing order. The neighborhood can be chosen either symmetrically, containing $k / 2$ observations to the left of $x_{i}$ and the same number to the right, or it ran be chosen to contain the $k$ nearest neighbors of $x_{i}$, including $x_{i}$. (We assume that $k / 2$ is computed by integer division.) There are no general results on which of thes, two possibibities is better statistically. ihe nearest neighbors approach generalizes to higher dimensions, but the chorce of a symmetric neighborhood is computationaliy simpler in that exactiy one point enters and one point leaves the neighborhood as one moves from observation 1 to observation $1+i$. We will, in the following, use symnetric neighborhoods: The boundaries, where it is not possible to keep $N$ symmetric, nave to be treated specially; a commonly used adjustiment is to shrink the neighborhood so that for $1=1$ and $i=n$, one averages oniy over $k / 2+1$ observations. With these conventions, the moving average smoother is defined by

$$
s\left(x_{i}\right)=\operatorname{mean}(y) \mid \max (1-k / 2, i) \leqslant J \leqslant \min (1+k / 2, n)
$$

obvously, the mean does not have to be recomputed every time. It can be
updated, reducing the computation from nk to $n$. Such updating can be done for all the smoothers we will consider, and is highly desirable because in typical apolications $k i s 5 \%$ to $30 \%$ of $n$, and thus the savings are substantial. The simple moving average smoother has some serious shortcomings: one disturbing property is that it does not reproduce straight liי.es if the abscissa values are not equi-spaced: Another disturbing feature is the bad behaviour at the boundaries. If, for example, the slope of the underiying function $f$ is positive at the right boundary, the estimate for observations close to the boundary will be biased downwards; if the slope is negative, the estimate is biased upwards. Both problems can be alleviated by fitting a least squares straight line $L$ to the observations in the neighborhood instead of fitting a constant and taking the value of the line at $x$, as the smoothed value. This obviously solves boch problems mentioned above. For the computation, again updating formulas can be used. The slope $\beta$ and intercept af the least squares straight line through a set of points $\left(x_{1}, y_{1}\right) \ldots\left(x_{m}, y_{m}\right)$ are given by
$\alpha=\bar{y}_{m}-\beta \bar{x}_{m}$

$$
B=\frac{C_{m}}{V_{m}}
$$

with

$$
\begin{gathered}
\bar{x}_{m}=\sum x_{i} / m \\
\bar{y}_{m}=\sum u_{i} / m \\
c_{m}=\sum\left(x_{1}-\bar{x}_{m}\right)\left(y_{i}-\bar{y}_{m}\right) \\
v_{m}=\sum\left(x_{i}-\bar{x}_{m}\right)
\end{gathered}
$$

When we want to add an observation $\left(x_{m+1}, y_{m+1}\right)$, we can make use of the following easily derived formulas:

$$
\begin{aligned}
& \bar{x}_{m+1}=\left(m \bar{x}_{m}+x_{m+1}\right) /(m+1) \\
& \bar{v}_{m+1}=\left(m \bar{y}_{m}+y_{m+1}\right) /(m+1), \\
& c_{m+1}=c_{m}+\frac{m+1}{m}\left(x_{m+1}-\bar{x}_{m+1}\right)\left(y_{m+1}-\bar{v}_{m+1}\right) \\
& v_{m+1}=v_{m}+\frac{m+1}{m}\left(x_{m+1}-\bar{x}_{m+1}\right)^{2} .
\end{aligned}
$$

Analogous formulas can obviously be used for removal of an observation from the set.

## 4. Choice of Span

The most important choice in the use of a local averaging smoother is the chorce of the span value. If the smoother is regarded as a curve estimator, then the span controls the trade of $\ddagger$ between bias and variance of the estimate. We lliustrate this for the case of a simple moving average smoother.: In this case, the smoothed value at point $x_{i}$ is given by

$$
s(x,)=\frac{1}{k} \sum_{1-k / 2}^{i+k / 2} y,
$$

If we assume that the errors $\epsilon_{i}$ are 1.1 . d. with experted value zero and yariance $\sigma^{2}$, then the expected squared error at point $x$, is

$$
\begin{equation*}
\operatorname{ESE}\left(x_{i} \mid k\right)=\left(f\left(x_{i}\right)-\sum_{k}^{1} \sum_{1-k / 2}^{1+k / 2} f\left(x_{j}\right)\right)^{2}+\frac{1}{k} \sigma^{2} \tag{4}
\end{equation*}
$$

Increasing the span will (if $\left.d^{2} f / i x^{2} \neq 0\right)$ increase the first term, the bias component of the estimation error and decrease ine second term, the
variance component; decreasing the span will have the opposite effect. The span should be chosen such that both compnents of the error are reasonably balanced. Stated more geometrically, a larger span makes the smooth appear less wiggly by more strongly damping high frequency components of the series $(x, y i)$.

We have, so far, said rothing useful on how to chosse the span in practice. The advice given above on balancing bias and variance is not very helpful because both $f$ and the variance of the random error are unknown:

One can estimate the rifinal span value in a particular situation as that value that minimizes an estimate for the integrated squared error

$$
I^{2}(k)=\int \operatorname{ESE}(x \mid k) d F(x) .
$$

Using the average squared residuai of the data from the smooth

$$
\hat{i}^{2}(k)=-\sum_{i=1}^{n}[y,-s(x, \mid k)]^{2}
$$

for this purpose 15 not appropriate since this is always minimized by the span value $k=1$. A better estimate is provided by a method referred to as "cross-valida: un" (M. Stone, 1974) or "predictive sample reuse" (Geisser, 1975) Each observation is in turn deleted and the value of the smooth $s_{1}, 1(x, \mid k)$ at $x$, is calculated from the other $n-1$ observations. The cross-validated estimate inf the integrated square erro: is

$$
\begin{equation*}
i^{2} c_{r}(k)=\frac{1}{n} \sum_{1=1}^{n}\left[y_{1} \cdots s_{1},(x, \mid k)\right]^{2} . \tag{5}
\end{equation*}
$$

Clearly, E[ $\left.\hat{l}^{2} c v\right]$ equals the expected squared error obtained by applying the procedure to a sample of $n-1$ observations from the same distibution. The cross-validated estimate for the optimal span value is taken to be the value $k_{c v}$ that minimizes (5),

$$
k_{c v}=\min _{0<k S N}^{-1} \quad \hat{I}^{2} c v(k) .
$$

Model selection through c:oss-validation has been remarkably successful in a wide varioty of situations (see M. Stone, 1974, Geisser, 1975, Craven and Wahba, 1957, C. Stone, 1981).

For the moving average smoothers discussed in the previous section, the deleted smooth estimates $s(i)\left(x_{i} \mid k\right)$ are especially easy to compute; each observation is simply deleted from the neighborhood used to compute its local straight line fit. Again. the use of updating formulas makes this computation very rapid. As one moves from observation $i$ to $1+1$, exactly two observations enter the neighborhood ( $i$ and $i+k / 2+1$ ) and exactly two leave it $(1+1$ and $i-k / 2)$. The (deleted) residual squared

$$
\begin{equation*}
r^{2}(i)=\left[y_{i}-e_{(i)}\left(x_{i} \mid k\right)\right]^{2} \tag{6}
\end{equation*}
$$

is computed for each observation and then averaged over all observations,

$$
\begin{equation*}
\hat{l}^{2} \operatorname{cv}(k)=\frac{1}{n} \sum_{1=1}^{n} r^{2}(i) . \tag{7}
\end{equation*}
$$

For small to moderate changes in $k$, $\hat{i}^{2} c y(k)$ changes very little so that it is adequate to evaluate it for several (4 to 7) discrete values of $k$ in the range $[0<k / n \leq 1]$. The value of $k$ corresponding to the smallest of these values is then used. This can be accomp!ished by maintaining several running average smoothers - one for each span value - in the pass over the data, thus keeping the computational cost linear in $n$.

So far, we have been assuming that the span is constant over the whole range of predictor values. This is not optimal if either the variance of the random component or the second derivative of the underlying function f change over the range of predictor values. A local increase in error variance would call for an increase in span, whereas an increase in second derivative of $f$ would require a decrease: It 15 , therefore, desirable to allow the span value to adapt to these changing conditions. This requires ihat the optimal span value be choosen locally rather than choosing a single global value, Again, the form of moving average smoothers make this especially easy; the (deleted) residual squared (5) -for each of the several $k$ values- $1 s$ averaged locally in a neightorhood of each observation

$$
\begin{equation*}
i^{2} c y\left(k ; x_{i}\right)=\frac{1}{L} \sum_{\ell=1-L / 2}^{1+L / 2} r^{2}(\ell)\left(x_{l} \mid k\right) \tag{8}
\end{equation*}
$$

rather than ginbally over all observations (7). Note that (8) alsn has the form of a simple moving average smoother and can therefore be computed rapidly through the use of updating formulas. The value that minimizes ( 8 )

$$
\begin{equation*}
\hat{k}_{c v}\left(x_{i}\right)=\min _{0<k \leq N} \quad \hat{I}^{2} c v\left(k ; x_{1}\right) \tag{9}
\end{equation*}
$$

is the span value used for the ith observation:

Most often the shape of ${ }^{2} \mathrm{cv}\left(k_{i} x_{i}\right)$ near its mlonmun value is shallou and asymmetric, increasing mure slowly in the direction of sinaller $k$ values: Variability in the estimate $\hat{\mathrm{I}}^{2} \mathrm{cv}$, therefore, causes $\hat{\mathrm{K}}_{\mathrm{c}}$ v to be highly yariable and biased :oward smaller values. i!though this has little effect on the qualify of the resulting smooth in terms of expected
squared eiror (ESE), it does effect its aesthetic quality since, for comparabie ESE, the less smooth solution tends to be selected. This can be remedied by forcing the procedure to take the smoothest solution in these circumstances. Epecifically, the largest span value $\hat{k}^{*} c y$ for which

$$
\begin{equation*}
\hat{I}^{2} c v^{\prime}\left(k^{*} c v i x i\right) \leq(1+\alpha) \min _{0<k \leq N} \hat{I}^{2} c v\left(k ; x_{i} ;\right. \tag{10}
\end{equation*}
$$

is used for the ith observation. Here a loosely controls an upper linit on the fraction of ESE that is to be sacrificed for the goal of smoothness. Valuss in the range $0.05 \leq a \leq 0.2$ are reasonable.

Since the optimal span value is estimated separately for each observation, its size Ean vary substantially over the range of predictor values. However, since for close abscissa values the neighborhoods overlap considerably, this variation is constrained to be smooth. The degree of smoothness is controlled by the parameter $L$ (8) which can be regarded as a span for smoothing the (deleted) residuals squared from the original smooths: As with the original smoother, its optimal value can be estimated by cross-validation. To the extent that the variation of the ser ind der vative of $f$ or the variation in the random component is comparable to the variation of fitself, this second level of cross validation may be beneficial. Again, updating formulas make this relatively inexpensive. However, in most circumstances chucising a nominal value for $L(02 n$ to $0.3 n)$ is adequate.

It is imfortant to note that using cross-validated residuals as a basis for choosing span value is highly sen, itive to lack of independence among the $\epsilon_{1}(2)$ as ordered on $x$. If there is a large positive (negative) correlation among observations with similar $x$ vaiues,
substantial under (over) estimates will result. In situations where a high degree of auto-correlation is suspected, these span selection procedures should be used with caution.

Figure 1 illustrates the application of this smoothing algorithm to an artificial data set. (A FORTRAN subroutine implementing this algorithm is listed in Appendix 1.) The data for this examole consists of $M=200$ pairs ( $x_{i}, y_{i}$ ) with the $x_{i}$ drawn randomiy (ild) from a uniform distribution in the interval $[0,1]$. The $y_{i}$ are obtained from

$$
y_{i}=\sin \left[2 \pi\left(1-x_{i}\right)^{2}\right]+x_{i} \in i
$$

with the $\epsilon$; iid standard normal. The parameter ALPHA [a in (10)] was set to 0.1 and RESPAN $[L / n \ln (8)]$ was set to 0.25 (see Appendix 1). This example simulates a situation in which both the curvature of decreases ard the variance of the random component increases with increasing $x$. Figure la is a scatterplot of the simulated data. Figure ib also shows this scatterplot, but with the resulting smooth superimposed. The height of the curve near the botom indicates the span value chosen at each $x$, The span is seen to increase with $x$ to account for the increasing noise, as well as to take advantage of the decreasing curvature of f. (For $x$ ) 0.7, the span has reached the largest value provided in the program, $k / N=0.7$.$) Figure lc is the same as figure lb except that the curve$ $y=f(x)=\sin \left[2 \pi(1-x)^{2}\right]$ is superimposed for reference. The resulting smooth 15 seen to estmate the underlying f reasonably well. Note that for a linear function $y=a x+b$ (zero curvature) the smoother will tend to use a constant (maximum) span value regaraless of (the variation of) the aminlitude of the noise.

## 5. Keducing Computation by Binning

$$
\begin{aligned}
& \left.u_{i}=\text { mean }\left(x_{( } ;-1\right) m+1 \ldots x_{i m}\right) ; \\
& v_{i}=\operatorname{mean}\left(y_{( }(i-1) m+1 \ldots y_{i m}\right) .
\end{aligned}
$$

Then apply the smoother described above to the $\left\{u_{1}, v_{1}\right) \ldots\left(u_{n}, m, v_{n}, m\right)$. The smooth for predictor values $x$; not among $u_{1} \ldots u_{n / m}$ can be obtained by linear interpolation or, at the boundaries, by extrapolation.

The computing time for lie smoother grows linearly in the number of observations, and so binning reduces the run time of the smoother roughly by a factor of $m$.

Figure 2 shows the results of applying the smoother to eample of $n=500$ observations generated from the same model as the data shown in figure 1, with the results of applying the binning procedure with $m=5$ superimposed. The quality of the smooth is seen to suffer very little while the computation has been substantially reduceu.

## 6. Resistance

As for all data analytic procedures, it is highly desirable for a scatterpiot smoother to be resistant against occasional outliers in the data. (All our analysis is conditional on the observed predictor values; nutlier thus means outlier in response.) The smoother described in Sections 4 and 5 clearly is not resistant. One way to overcome this limitation is to first screen the data with a rejection rule identifying outliers, and then apply the smoother to the cleaned data set.

We suggest a rejection rule based on running medians. A running median smoother with span $k$ is defined by

$$
s\left(x_{i}\right)=\operatorname{med}\left(!;-k / 2 \ldots y_{i}+k / 2\right)
$$

The ends of the sequence must be treated specially, most simply by replicating the outermost values defined above. The rejection rule makes five passes over the data:

1) Compute a running median smooth $s$.
2) Replace $s\left(x_{i}\right)$ by $s^{*}\left(x_{1}\right)$ ubtained by linearly interpolating between $\left(x_{1}, 1, s\left(x_{i}, 1\right)\right)$ and $\left(x_{i+1}, s\left(x_{i}, 1\right)\right)$ : The purpose of this step is to ensure a more realistic estimate of spread in steps (3) and (4) fur monotone (sub)sequences, which are exactly reproduced by a running median.
3) Smooth the absolute residuals $\left|r_{1}\right|=\left|y_{1}-s^{*}\left(x_{i}\right)\right|$ by a running median and obtain a sequence $v, \ldots v_{1}$ of local spread estrmates $v^{*}$.
4) Smooth the spquence of lucal spread estimates by a moving
```
    average with span f*n and obtain smoothed spreads v*i. This
        makes the spread estimates more stable. The same effect could
        be achieved by increasing the span of the running medians in
        Step (3); however, this would be more expensive
        computationally. In the code given in Appendix 2, the
        constant f is set to 0.3.
        5) Flag all observations for which | ri| 2c.v*i. In the code, c
        1s set to 4.5.
Some details related to the treatment of ties have been omittcd. A
FORTRAN subroutine implementing this algorithm is listed in Appendix 2.
```

The span for the running medians in Steps (1) and (3) is chosen to be increasing with the sample size $n$ (see rable 2). A mativation for our particular choices is given in Chapter 7. We use the same span in both steps, aithough there is no inherent need to do so.

Figure 3 a shows the result of applying the rejection rule to an artificial data set. The true underlying function is a sine wave. The predictors are uniformly distributed in $[0,2 \pi]$; the random errors are Gaussian with standard deviation 0.3. Outliers ocsur with protability 0.2 ; they were generated by adding a Gaussian with standard deviation 2.4 to the original observation. Observations flagged as outliers by the rejection rule are marked by squares. Figure 3 b shows the results of applying the rejection rule to a real data set.
7. Resistance of Running Medians

The choice of span $k$ for the running medians in Steps, ,) and (3)
gives rise to rather interest ng questions. Somewhat vagueiy stated, the rejection rule will be able to detect extreme outliers as long as these running medians do not break doun. We will now define precisely how we measure the degree of resistance of a smoother, and give results on the dependence of the resistance of a running median smoother on the span.

#### Abstract

Assume we want to smooth a sequence of length $n$. Responses can be either "good" or "bad", that is, good observations or outliers. We define random variables $b_{i} \ldots b_{n} b y b_{i}=0$ if $y_{i}$ is good, $b_{i}=1$ if $y_{i}$ is an outlier. Assume that $\operatorname{Prob}\left(b_{i}=1\right)=p$ and that the $b_{i}$ are independent. (As noted by Mallows v1980), the latter assumption might not always be realistic; outliers in time series sometimes ume in bursts.) A smoothed value $s, ~ i s ~ c a l l e d ~ b a d ~ i f ~ i t ~ c a n ~ b e ~ m a d e ~ a r b i t r a r i l y ~$ large by suitable choice of the reponse values for the bad observations. A smoother is said to suffer a breakdown if one or more of the smoothed values $s i$ are bad. The probability that this happens under the above model for the $b$ is called the breakdown probability of the smoother. It will generally depend on $p$ and $n$. A smoother with breakdown probability (1-p)n is called nonresistant: (For a different definition of breakdown probability, see Mallows (1980).)

> We will now devise an approximate formula for the span necessary to guarantee an upper bound on the briakdown probability as a function of $n$ and $p=\operatorname{prob}(b,=1)$. For that purpose, we define new random vari.dules $s_{1} \ldots s_{n-k+1}$ by

$$
s_{1}=\sum_{1}^{1+k-1} b_{1}
$$

A running median smoother suffers a breakdown if among any consecutive $k$ observations more than $k / 2$ are bad; i.e., if $\max s i>k / 2$. This probability does not seem to be simple to evaluate, but it is easy to obtain an upper bound in terms of the binomial probability Prob!i(k,p) , $k / 2$, using the Bonferroni inequality:

```
Prob(max si > k/2) \ (n-k+1) Prob(B(k,p) >k/2).
```

This inequality provides an estimate for the span needed to guarantee a certain upper bound on the breakdown probability for given $n$ and $p$. Table 1 gives estimates of the necessary span $k$ for breakdown probability bounded by 0.05 , and several values of $n$ and $p(n=25,50,100,200,400,800$; $p=0.05,0.1,0.21$. For a comparison, we also list the percentage of breakdowns actually observed in thousand randomly generated Bernoulli sequences for the estimated value of $k$, and the smallest value of $k$ resulting in 50 or fewer breakdowns. The results show that the Bonferron estimate is close, especially for $p=0.05$ and $p=0.1$ where Prob( $B(k, p)>k / 2)$ is small; this is in agreement with experience gained in using the Bonferroni inequality in multiple comparisons: The span of the running medians in steps (1) and (3) of the rejection rule described in Chapter 6 was chosen to guarantee a breakdown probability of less than 0.05 for probatility $p=0.1$ of obtaining an outiler.

Another interesting question is how fast the span $k(n)$ must grow as a function of $n$ with everything else fixed. This question has beell answered by $P$. Erdös and $A$ : Renyl (1970):

Theorem: If $k(n)=c l n n$ then

$$
\text { Prob! } \left.11 m \max _{1, \infty} \frac{s_{i}}{-1 \leq 1 \leq n-k+1}=a\right)=1 \text {, }
$$

where $a$ is related to c via the equation

$$
\frac{-1}{c}=\ln (p(1-p))+(1-p-\alpha)\left(\ln \frac{\alpha}{1-\alpha}-\ln \frac{p}{1-p},\right.
$$

for a > c .

This theorem ו. a special case of Erdös and Renyi's theorem 2. It can be applied to our situation as follows: choose $\alpha=1 / 2-\varepsilon$. Then there exists ar $n_{0}$ such that for all $n$ ) no we have max $s_{i}$ ( k/2 for almost all sampling sequerces. In addition, Erdös and Renyi show that

- If $k$ grows slower than $\ln n(k(n) / \ln n \rightarrow 0$,$) , then for a'l but$ finitely many values of $n$, $\max s_{i}=k$ for almost ail sampling sequences. ("k cannot grow slawer than $\ln \mathrm{n}^{\circ \prime}$.)
- If $k$ grows faster than $\ln n(k(n) / \ln n+\infty)$, then lim max $s i=k p$ for almost all sampling sequences; i.e:, the strong law of large numbers applies. (" $k$ does not have to grow faster than $\ln n "$.)

## 6. An Updating Algorithm for Running Medians

There is a straightforward way to compute running medians: obtain the median of each consecutive k-tupel by sorting it: That can be substantially improved upon by making use of the fact that the set of responses defining $s_{1+1}$ is almost the same as the set of responses defining si; only $y_{1 m}=y_{1+k / 2}$; has to be added, and yout $=y_{1} \cdot k_{1}$ has to be deleted. The following rules are easy to verify:

- If $y_{1 n}=s_{i}$, then $s_{i+1}=s_{i}$.
- If $\left.v_{1 n}\right\rangle s_{1}$ and yout $s_{1}$ or if $y_{1 n}\left\langle s_{1}\right.$ and vout < $s_{i}$, then $s_{1+1}=$ $\mathbf{s}_{1}$.

So in the case of random data, we have to do nothing but make these tests nalf the time.

- If $\left.y_{i n}\right\rangle$ s: and yout $\left\langle s_{i}\right.$, then let $k^{+}$denote the number of observations in the new span that are bigger than $s i$. If $K^{+}<k / 2$, then $s_{i+1}=$ ii, else $s_{i+1}$ is the smallest observation strictly bigger than si. The analog of that is true $1 f y_{i n}\langle s i$ and yout>si.
- If yin> $s_{i}$ and yout $=s_{i}$, then define $k^{+}$as above. $\quad$ If $k *=k / 2$, then $s_{i+1}$ is the smaliest observation in the span strictly bigger than si; else si+1 is the smallest observation in the span that is bigger than or equal to si. The analug of that is true if $y$ in $<s_{i}$ and $v_{\text {out }}=5$;

In appendix 2, we give a FORTRAN subroutine that implements the algorithm outlined above:

For random data, the algorithm will take $O(n k)$ operations. It is poss:ble to reduce that to $O(n \log k)$ by organizing the observations in the span into a binary tree which is kept balanced as observations are moved in and out (AVL-tree; see Knuth (1973), pp 451). Unfortunately, for the range of $k$ that we have in mind (about 20), log $k$ is not enough smaller than $k$ to compensati for the increased overhead.
9. Discusision

Cleveland (1979) has suggested a scatterplot smoother also based on local linear fits. It differs from the one described in this report mainly in three respects:

- Ii does not use variable span.
- In the fit of the local strainht line determing the smooth $s\left(x_{1}\right)$ for
predictor valus $x_{i}$, the observations are weighted according to their distance from $x_{1}$. observations towarus the extremes of the span receive lower weights than observations with predictor values close to $x_{i}$. Asymptotic calculations suggest that assigning unequal weights should reduce the error of the curve estimate, but there is no evidence that it makes a substantial difference for sample sizes occurring in practice. It dess, however, produce a smoother looking estimate.
- The procedure derives its resistance properties not from data screening with rejection rule. Instead, each of the local straight lines is fitted, not by least squares, but by a resistart fitting procedure.

Updating formulas cannet be used in this scheme, making it comparatively expensive in terms of computing. To reduce computation, Cleveland suggests evaluating the smooth only for every m-th predictor value. The parameter $m$ iere flays a similar role as our bin size; it would be chosen as a fraction of $k$. We developed our smoothing procedure because variable span is often important, and because the use of updating formulas dramatically reduces computation.

Another class of procedures suggested for smoothing are procedures based on splines. A spline function s of order: with knots at z....zk 15 a function satisfying the foilowing two ronditions:

- In each of the intervals $\left(-\infty, z_{1}\right),\left(z_{1}, z_{z}\right) \ldots\left(z_{k}=\eta_{k}\right),\left(z_{k}, \infty\right), \quad s$ is a polynomial oi degree $2-1$;
- shas $\AA$ - 2 continuous delivatives.

One way to use spline functions in scatterplot smoothing is to fit a spline function with knots $z_{1} \ldots z_{k}$ to the data $\left(x_{1}, y_{1}\right) \ldots\left(x_{n}, y_{n}\right)$, either by least squares or by some resistant method. The degree of smoothness is determined by the number and position of the knots. A major disadvantage of this method is that $\alpha+1$ parameters must be chosen: the number and the positions of the knots. Usually some heuristic procedure is used to place the knots once $k$ has been fixed (Jupp, 1978). This leaves the number of knots to be determined. This number plays the rale of the span in defermining the degree of smoothing: Unfortunately, the output of the smoother can depend on $k$ in very nonlinear way; it is easy to construct examples where the addition of one more knot substantially decreases the residual sum of squares, whereas further knots hardly make any difference. This makes $k$ more difficult to choose than the span in local averaging smoother: furthermore, least squares fit of splines is substantially slower so that choosing $k$ through crossvalidation is usually too experisive.

Another way is to use smoothing spiines in the sense of Reinsch (196\%): A smoothing spline $s$ of order $2 \ell$ for smoothing parameter $\lambda$ is the function that minimizes

$$
\sum\left(y_{1}-f\left(x_{i}\right)\right)^{2}+\lambda \int_{x_{1}}^{x_{n}} f(f) z(x) d x
$$

among all functions f with 2 derivaties. The solution really turns out to be a spline function of order $2 \Omega$ with knots $x_{1} \ldots x_{n}$; the name is thus Justified. The larger $\lambda$ is chosen, the smoother $s$ becomes; thus, $\lambda$ here plays the rule of the spar. Computation of the splire for given $\lambda$ requires the solution of a banded $n{ }^{*} n$ linear system $A$ drawhack of the
method, as described here, is that it is impossible to intain an
intuitive feeling for the choice cf $\lambda$ in a given example. So, one
usually fixes not $\lambda$, but the residual sum of squares around the smooth.
The corresponding value of $\lambda$ then has to be found iteratively by
repeatedly solving the minimization problem. This substantially
increases the necessary amount of computation. Algorithms to determine
the optimal $\lambda$ by cross-valldation usually require computation of the
singular value decomposition of an nxn matrix; they are expensive and
infeasible for sample sizes larger ina: $200-300$.

To summarize, the local averaging smoother descriled in this report has two desirable properties that set it apart $2 m$ other scatterplot smoothers: it is very fast to compute and the value of the parameter that controls the amount of smoothing is optimized locally (through crossvalidation), allowing it to change over the range of predictor values,

15 KEY WORDS (Continue an reverze elde if neceseary and ldentify by block number)
rot.stness, smoothing, curve estimation, regression, outlier detecion

A variable span scatturplot smoother based on local linear fits is described. Local cross-validation is used to estimate the optimal span as a function of abscissa value. A rejection rule is suggested to make the smoother resistant against outliers. Computationaily efficient algorithms making use of updating formulas and corresponding FORTRAN subroutines are presented.
